Abstract. We address and solve a number of problems in the context of a robot surveillance system based on a pair of dioptric (fisheye) cameras. These cameras provide a hemispherical field of view that covers the whole robot workspace, with some advantages over catadioptric systems, but there is little previous work about them. Then, we had to devise and implement a number of novel techniques to achieve robust tracking of moving objects in dynamic, unknown environments from color image sequences in real time. In particular, we present a new two-phase adaptive background model that exhibits a robust performance when there are unexpected changes in the scene such as sudden illumination changes, blinking of computer screens, shadows or changes induced by camera motion or sensor noise. The system is also capable of tracking the detected objects when they are not in movement. We also deal with fisheye camera calibration to estimate both intrinsic and extrinsic parameters, as well as the estimation of the distance between the system and the detected objects with our dioptric stereo system. Experimental results are reported.

1 Introduction

Robotics research, from its beginning, has been always focused on building robots which behave and look like human beings. Thus, from industrial robots, which act in a restricted, controlled, well-known environment, robot development was conducted to emulate alive beings in their natural environment, that is, a dynamic, unknown environment. In the case of mimicking human being behaviors, a key issue is how to perform manipulation tasks, such as picking up or carrying objects. However, as this kind of actions implies an interaction with the environment, they should be performed by guaranteeing the safety of all elements present in robot workspace at each time, specially when they are human beings.

Although some devices have been developed to avoid collisions, such as, for instance, cages, laser fencing or visual acoustic signals, they considerably restrict system autonomy and flexibility. From the available robot sensors, cameras might be suitable for this goal, since they are an important source of information. On the one hand, they allow a robot system to identify interest objects, that is, objects it must interact with, from some previous knowledge such as its color, its

* The authors are with the Robotic Intelligence Lab, Jaume-I University, Spain
shape or other distinctive features. On the other hand, in a real, unknown environment, from visual input, it is possible to build a map of the environment from which a collision-free path might be generated. Nevertheless, it is not straightforward to successfully deal with this safety issue by using traditional cameras due to its limited field of view. That constrain could not be removed by combining several images captured by rotating a camera or strategically positioning a set of them, because it is necessary to establish any feature correspondence between a lot of images at any time. This processing entails a high computational cost which makes them fail for real-time tasks.

An effective way is to combine mirrors with conventional imaging systems [1] [2] [3]. The obtained devices are called catadioptric systems. Moreover, if there is a single viewpoint, they are referred as central catadioptric systems [4]. This is a desired feature in such imaging systems since it describes world-image mapping. In fact, a single viewpoint implies that all rays go through a 3D point and its projection on the image plane goes through a single point in the 3D space. Conventional perspective cameras are devices of a single viewpoint, for example. Although the central catadioptric imaging can be highly advantageous, they unfortunately exhibit a dead area in the centre of the image what can be an important drawback in some applications.

With the aim of overcoming all the above drawbacks, a dioptric system was used. Dioptric systems, also called fisheye cameras, are systems which combine a fisheye lens with a conventional camera [4] [5]. Thus, a conventional lens is changed by one of these lenses which has a short focal length what allows cameras to see objects in an hemisphere. Although fisheye devices present several advantages in front of catadioptric sensors such as no presence of dead areas in the captured images, a unique model for this kind of cameras does not exist unlike central catadioptric ones [6].

In this work, we have focused on dioptric systems to implement a robot surveillance application for fast and robust tracking of moving objects in dynamic, unknown environments. Although our final goal is to design an autonomous, mobile manipulation robot system, here we present the first stage: novel techniques for robust tracking of moving objects in dynamic, unknown environments from color image sequences such that manipulation tasks could be safely performed in real time when the robot system is not moving. For that, three different related problems have been tackled:

– moving object detection
– object tracking
– distance estimation from the system to the detected objects

First of all, a new robust adaptive background model has been designed. It allows the system to adapt to different unexpected changes in the scene such as sudden illumination changes, blinking of computer screens, shadows or changes induced by camera motion or sensor noise. Then, tracking process from two omnidirectional images takes place. Finally, the estimation of the distance between the system and the detected objects must be done by using an additional method.
In this case, information about the 3D localization of the detected objects with respect to the system was obtained from a dioptric stereo system.

Thus, the structure of this paper is as follows: the new robust adaptive background model is described in Section 2, while in Section 3 the tracking process is introduced. An epipolar geometry study of a dioptric stereo system is presented in Section 4. Some experimental results are presented in Section 5, and discussed in Section 6.

2 Moving Object Detection

Research in human and object detection has taken a number of forms. Well-known techniques to segment objects from a captured image are thresholding or frame subtraction. Thus, experiments to obtain a robotic assistant in which a person is detected and then followed by a mobile robot \[7\] \[8\] \[9\] \[10\] have been carried out. Nevertheless, in spite of the fact that existing algorithms are very fast and easy to use, image processing for object identification is very poor since it is color- and/or face-based. This restricts their utility because it is not viable to track objects of a determined color, which has also to be significantly different from the background, or it constrains people to always face the vision system.

With regard to the thresholding technique, the selection of the reference value is a problem because it is not possible to automatically determine it when a robot is interacting with an unknown, dynamic environment and the objects within it can be anything, because most of them are based on histogram properties which are also unknown in these work conditions \[11\].

Finally, although the image difference method provides a good detection of changing regions in an image, it is important to pay attention to several uncontrolled changes in the system environment which can produce multiple false negatives and make the system fail. These dynamic, uncontrolled changes can be divided into:

- minor dynamic factors, such as, for example, blinking of computer screens, shadows, mirror images on the glass windows, curtain movement or waving trees, as well as changes induced by camera motion, sensor noise, non-uniform attenuation or atmospheric absorption, among other factors
- sudden changes in illumination such as switching on/off a light or opening/closing a window

Different research has been developed to adapt to this changes. One of the most common is the background subtraction approach, which has been proposed by several researchers \[12\] \[13\] \[14\] \[15\] \[16\]. Basically, a background model, which is built after observing the scene several seconds, is used to identify moving objects by subtracting the new frame and the built background model. However, this approach presents two important drawbacks:

- everything observed when the background model is being built is considered background
– no sudden change in illumination occurs during the whole experiment

Therefore, a novel algorithm is proposed here. It is divided into two different phases, as can be seen in Fig. 2:

1. In the first phase, an initial background model is obtained by observing the scene during several seconds. However, unlike most background estimation algorithms, another technique for controlling the activity within the robot workspace is performed. With the aim of reducing the computational and time cost, this control is performed by means of a simple difference technique. In that way, there is no danger to damage people who approach the robot while this initial model is being built. Thus, basically, in this phase, a simple frame-difference approach is performed in order to detect moving objects within the robot workspace. Then, two consecutive morphological operations are applied to erase isolated points or lines caused by the dynamic factors mentioned above. In this point, two different tasks are carried out:
   – On the one hand, adaptive background model is updated with the values of the pixels classified as background in order to adapt it to some small changes which do not represent targets
   – On the other hand, a tracking process, which is explained in the next sections, is performed

2. In the second phase, detection and identification moving object process starts. When a human or another moving object enters in a room where the robot is, it is detected by means of a two-level processing:
   – pixel level, in which the adaptative background model, initially built in the previous phase, is used to classify pixels as foreground or background. It is possible because each pixel belonging to the moving object has an intensity value which does not fit into the background model. That is, the used background model associates a statistical distribution (defined by its mean color value and its variance) to each pixel of the image. Then, when an interest object enters and/or moves around the robot workspace, there will be a difference between the background model values and object’s pixel values. Actually, a criterion based on stored statistical information is defined to deal with this classification and it can be expressed as follows:

$$b(r, c) = \begin{cases} 1 & \text{if } |i(r, c) - \mu_{r,c}| > k \times \sigma_{r,c} \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

where $b(r, c)$ is the binary value of the pixel $(r, c)$ to be calculated, $i(r, c)$ represents pixel brightness in the current frame, $\mu_{r,c}$ and $\sigma_{r,c}$ are the mean and standard deviation values calculated by the background model respectively and $k$ is a constant value which depends on the point distribution
   – frame level, whereby the raw classification based on the background model is improved as well as the model is adapted when a global change in illumination occurs. A proper combination of substraction techniques
A dioptric stereo system for robust real-time tracking has been implemented. In that way, a different segmentation process is applied at frame level and it is used to improve the segmentation carried out at pixel level. Furthermore, this processing allows the system to identify global illumination changes. That is, it is assumed that a significant illumination change has taken place when there is a change in more pixels than a half of the image size. When an event of this type occurs, a new adaptative background model is built because if it was not done, the application would detect background pixels as moving objects, since the model is based on intensity values and a change in illumination produces a variation of them.

As in the previous phase, after properly segmenting an image, two consecutive morphological operations are applied to erase isolated points or lines caused by small dynamic factors. Later, pixels classified as background are incorporated to the adaptive background model, while foreground pixels are processed by applying a tracking method.

3 Tracking Moving Targets

Once targets to be tracked have been identified, the next step is to track them. For that, first of all, a connected-component labeling algorithm is performed. However, due to segmentation errors, it might be obtained more than one labeled component for the same target. Thus, a merge algorithm, based on neighbour-hood and feature similarity, is applied. Then, a minimum rounded rectangles are generated. After that, with the aim of performing the corresponding tracking, a pattern is built from each of them. In this case, a pattern is intended as the data structure such that allows the system to track the moving objects by means of matching an object in two consecutive frames even when it suffers a partial or whole occlusion.

Thus, in our case, a pattern is composed of two different things:

- a representative image of the target, that is, it is not possible to directly compare two images of the same object when they are provided by an omnidirectional image. It is due to the fact that every object has different orientation depending on its position inside the scene. So, several rotations would be necessary in order to correctly match the images of the same object in two different frames. Thus, it is necessary to apply a transformation from the circular omnidireccional image to a perspective one (see Fig. 2. This is done only for each region detected as object of interest since transformation of the whole image could become very high time-consuming.

- a feature array whose elements contain information about brightness and blob width and height, among other things, used to properly match to images of the same object in two consecutive frames as well as two stereo images

Therefore, on the one hand, representative images are compared with the extracted from the previous frame or the another stereo image. In this way, a pixel-similarity likelihood between representative images is obtained. On the other hand, a feature-similarity likelihood is generated from feature array comparison. Both likelihoods are properly combined to match two images from the same object in consecutive frames or frames taken from a diopttric stereo system.

4 Stereo System

For approximately determining the distance from the system to an objective we need to estimate the correspondence between omnidirectional images, that is, the epipolar equation.

From the point of view of stereo vision, an epipole is defined as the projection of the camera center on the image plane of another camera. Unlike traditional cameras, two epipoles are visible, since any camera is within the field of view of each other. For that reason, in the case of omnidirectional cameras, it is not necessary to use a third external object for stereo calibration. This is the idea in which Zhu et al [15] [16] based to implement a virtual stereovision system with a flexible baseline in order to detect, track and localize moving human subjects in...
unknown indoor environments. In the literature, other approaches developed for catadiotropic systems can be found [16] [17] [18] [19]. However, even though there is almost no work with dioptric stereo systems, we have implemented a process to estimate the distance from the dioptric stereo system to the detected objects.

The guidelines of the distance estimation method are as follows:

- a matching process between images taken by different cameras is done. First, the adaptive background model at two levels is independently performed for the images captured by each camera. Then, each detected blob is described by means of a feature array whose elements contain information about brightness and blob width and height, among other things. Next, each feature array is compared with all the detected blobs in the frame taken by the other camera in the system, while the matching process included in the implemented moving object detection method is simultaneously performed. Thus, a similarity likelihood is calculated and a matching decision is made based on it.
– detection of the other camera in each frame, as it is depicted in Fig. 3. In fact, this step is necessary to be performed only once because the baseline of the stereo system is fixed.
– estimation of the distance with respect to each camera from triangulation geometry, as it is shown in Fig. 3. The triangle to solve is determined by the projection ray of a 3D point of the real world on each plane image as well as the projection ray of the center of the other camera of the system. It is possible thanks to the calibration step since the projection rays can be estimated, as mentioned above.

5 Experimental Results

Two different experiments have been carried out to check the designed application performance. First, the performance of the moving object detection was evaluated by using only one fisheye camera. After that, the obtained estimation of the detected object distance through our dioptric stereo system was analysed. In this section, some of these results are provided.

5.1 Experimental set up

For both kinds of experiments carried out, a mobile manipulator which incorporates a visual system composed of 2 fisheye cameras mounted on the robot base, pointing upwards to the ceiling, to guarantee the safety in its whole workspace. Figs. 4 depicts our experimental setup, which consists of a mobile Nomadic XR4000 base, a Mitsubishi PA10 arm, and two fisheye cameras (SSC-DC330P third-inch color cameras [20] with fish-eye vari-focal lenses YV2.2x1.4A-2, which provide 185 degree field of view).

Thus, on the one hand, a single fisheye camera was used to evaluate the moving object detection performance. The robot system was located in the center of our laboratory where almost all the space was covered and where most of the uncontrolled, dynamic factors named above were present (e.g. blinking of computer screens, shadows, mirror images on the glass windows or variations in illumination due to the different time of the day or the switch on/off a light). On the other hand, the dioptric system was used. In both cases, the images to process were acquired in 24-bit RGB color space with a 640x480 resolution.
5.2 Moving Object Detection Evaluation

As it was pointed out, the first series of experiments were to evaluate the performance of the novel adaptative, robust background model. For that, illumination conditions and object positions were changed. Two sequences of the images as a result of applying the novel updated background model under the same illumination conditions is depicted in Fig. 5. As it can be seen, the method is able to visually track moving objects without constraints such as clothes color or illumination.

In a similar way, illumination conditions were changed and, as it is shown in Fig. 6, the obtained results were also successful.
6 Conclusions

In this paper, a robust visual application to detect and track moving objects within a robot workspace has been presented based on a pair of fisheye cameras. These cameras have the clear advantage of covering the whole workspace without resulting in a time consuming application, but there is little previous work about this kind of devices. Consequently, we had to implement novel techniques to achieve our goal.

Thus, the first subgoal was to design a process to detect moving objects within the observed scene. After studying several factors which can affect the detection process, a novel adaptive background model has been implemented where constraints such as waiting a period of time to build the initial background or illumination conditions do not exist. In a similar way, it is also capable of tracking the detected objects when they are not in movement. In addition, the designed method includes a matching process between two consecutive frames.

The next step is to estimate the distance from the detected objects to the system. For that, a stereo dioptric system with fixed baseline has been built. Therefore, it was necessary to perform a calibration process in order to obtain the fundamental matrix. Three different toolbox were tested, but only two were used in the end. Finally, a method to estimate distance from the objects to the system was implemented. In this case, a triangulation technique is used. It is possible to perform because the cameras can see each other. It must be taken into account that epipolar geometry of the stereo dioptric systems was not used, although the combination of that with the current implementation in order to improve the accuracy in the matching process is part of our future work.
